Abstract---For a better knowledge of how viruses enter cells, the associations that are created between the viral glycoproteins and associated human receptors must be studied. The spike glycoprotein (S-glycoprotein) of the new coronavirus SARS-CoV-2 mediates entrance into host cells, and the cellular receptor angiotensin-converting enzyme 2 (ACE-2) has been discovered. The goal of our research was to evaluate the physiological interactions between the SARSCoV-2 and the human cell receptor ACE-2. Modifications were

discovered in the S1 monomer of the receptor-binding domain of spikes using an in silico analysis. The observed modifications have a considerable impact on the interlinkage between the SARS-CoV-2 spike and ACE-2. According to the research outcome, the SARS-CoV-2 spikes protein has a strong attraction for the human ACE-2 receptor than the Bat-CoV spikes does. Further, the presence of two loops throughout the SARS-CoV-2 receptor binding domain (RBD) may facilitate binding to the ACE-2 (receptor) through enhancing the quantity of atoms implicated. The reason SARS-CoV-2 binds to substrates with higher binding energies than SARS-CoV may be due to longer capping loops and changed amino acids.

Keywords--Coronavirus, Angiotensin-converting enzyme 2, Physiological interaction, Spikes protein.

Introduction

In Wuhan, China, in December 2019, a deadly atypical pneumonia outbreak that was later named coronavirus disease-19 was revealed to be brought on by a novel coronavirus (CoV). It was found that the new SARS-CoV-2, which triggered the SARS pandemic in 2002, had traits with the SARS-CoV that caused that epidemic.

The subsequent COVID-19 pandemic has developed into a significant scourge.

The SARS-CoV-2 genome is 94% equal to the BATCoV and 81% identical to the SARS-CoV genome [1-3].

The family Coronaviridae and the genus-coronavirus, which have all been connected to important epidemic outbreaks, include SARS-CoV-2 and well-known recombinant SARS-CoV. The positive-sense single-strand RNA of these viruses is roughly 34 kilobases long and is encapsulated [4]. The four main functional proteins present in virions are the spikes, cell wall, a protein coat, and nucleocapsid [5]. The receptor's host specificity and intracellular adhesion depend on the Spikes, which protrudes from the virion's outer membrane [6]. Angiotensin-converting enzyme 2 (ACE-2) is known to bind with the SARS-CoV and SARS-CoV-2 via spikes attach to protein [7,8]. However, it appears that ACE-2 serves as the primary basic ligand for both SARS-CoV and SARS-CoV-2 [9].

The interaction between the viral protein and its receptor on the cellular membranes is a critical step in the reproduction phase of the virus [10,11].

Additionally, the effectiveness of an infectious disease is significantly impacted by this mechanism. Many physical factors affect how proteins interact with one another. These components are influenced by the types of molecules and physiological interactions that take place between the receptor and ligand. The occurrence of residue that leads to an operationally preferable contact (lower free energy) may therefore encourage interaction kinematics and ultimately lead to the fusion process [12,13]. Therefore, the goal of our research was to evaluate the

physiological interactions among the SARS-CoV-2 and ACE-2 receptor cell of human.

Methods

Each sequence being studied received a distinct GenBank retrieval. Information from the protein data library was used to develop the spikes-related proteins model of the amino acid sequence of SARS-CoV-2. The virus Spikes from Bat-CoV and SARS-CoV-2 were modeled using Deep-PdbViewer 4.03 program and the SWISS-MODEL. The ideal models for the SARS-CoV-2 Spikes besides Bat-CoV were made by means of the crystal structures of PDB code 6ACD and SARS-CoV Spikes, respectively. These models underwent additional protein structural tuning. After the hydrogen atoms were added, the energy was improved by using fractional ions. Then, energy was reduced by enhancing the comparative locations of protein and water molecules and placing constraints on the protein chain to preserve global packing. Molecular dynamics (MD) simulations were performed on the collected devices using NAMD software. The created structures illustrated the least-energy framework from the MD simulation.

The crystal structures of the SARS-CoV spikes (Protein Data Bank number 6-ACK) and ACE-2 were retrieved from the Protein Sequences Bank (Protein data bank number 1R-42). Also looked at was the SARS-CoV-2 spikes' homologous framework. The aforementioned description indicates that the protein was prepared. Finally, the link between the virus spikes and ACE-2 receptor was created using molecular docking, adsorption configurations, and intensity estimates. There were two stages to this process. The ACE-2 receptor and the Spikes were first docked blindly using the Z-dock software. The resulting docking data was then analyzed and evaluated using the PRODIGY app's features. The results were then categorized and assessed while accounting for the main linking residues and relative intensities in each compound.

Results

The SARS-CoV as well as a phylogenetic analysis of the Spikes sequences of Bat-CoVs, including SARS-CoV-2 are revealed in figure 1. The outcomes are consistent with earlier research suggesting that SARS-CoV-2 originated after a Bat-CoV apart from the overflow that gave rise to SARS-CoV, and that the novel virus' most likely ancestor is a Bat-CoV of the *Rhinolophus* subsp. SARS-CoV-2 plus this Bat-whole CoV's spike share 97.70% of the same sequence (figure 1). The RBD of SARS-CoV and Bat-CoV from *Rhinolophus* subsp exhibits a variety of peptide losses and modifications when compared to SARS-CoV-2. Even though it resembled the SARS-CoV much more, the RBD of the Bat-CoV from *Rhinolophus* subsp likewise displayed several peptide alterations (figure 2).

Along with the crystalline configuration of the SARS-CoV Spikes, the homology structures of BatCoV (genbank accession code MG772933), BatCoV of *Rhinolophus* (*sinicus* subsp) and SARS-CoV-2 associated with the linking affinity domain placement in human ACE-2 were studied. The three virus-related spikes interact pretty similarly. The core section of contact with the hypothetical cell receptor homologue, which is made up of 15 residues organized in a β -sheet form,

is enclosed by two capping loops. Surprisingly, a comparison of the SARS-CoV-2 sequences and SARS-CoV revealed that there is a possibility that the 9 residues in the receptor-related domain shared by both viruses are evolutionarily conserved (69.9% similarity). The discovery of the human ACE-2 receptors has been connected to two crucial residues (487 and 479) in the SARS-CoV. N501 and Q493 are the residues that are equivalent to T487 and N479 in the SARS-CoV-2, respectively. These SARS-CoV-2 alterations could be beneficial for how the virus interacts with its receptor. These modifications are encouraged by the environment of the ACE-2 receptor to yield a large amount of electrical alleviating connections (table 1). The two capping loops in the binding domain are also probable to make a stronger connection with the cell surface receptor, as was already mentioned. According to the findings shown above, the aforementioned capping loops improve the electrical connections between the Spikes and the cell receptor. S432, N473, S472, D463, R426, Y436, T433, and T433 are among the residues in such capping loops in SARS-CoV that communicate with the receptor directly, whereas N487, F486, E484, G485, A475, Q474, V445, and Y473 and Y449 are common residues in SARS-CoV. The counter pairs present in the ACE-2 receptor is exposed in Table 1. Overall, the longer capping loops and improved protein interactions (Figure 3) may be to blame for greater SARS-CoV-2 binding energies (-16.7 Kcal/mol) than SARSCoV (15.1 Kcal/mol). These loops might therefore be essential and an intriguing sign of the hosting receptor virus Spikes along with punctual alterations (Table 2).

Bat-CoV	-8.2 kcal/mol	1.0×10^{-4}
SARS CoV (2002)	-15.1 kcal/mol	1.2×10^{-12}
SARS-CoV(2019)	-16.7 kcal/mol	5.0×10^{-14}

Discussion

The SARS-CoV-2RBD differs from SARS-CoV and Bat-SARS-CoVs because that it possesses several altered amino acids. Mutations in the Spike can alter a virus's tropism, adding additional hosts or increasing the pathogenicity of the virus [14].

HIV infection is a prominent illustration of how variations in the envelope proteins may alter the viral tropism. Changing the co-receptor from CCR5 to CXCR4, these changes boost the viral pathogenicity [15].

Surprisingly, our research displayed that these alterations are linked to the receptor's capability to connect with human ACE-2 receptors as well as its ability to increase identification. Two loops that are present throughout the SARS-CoV-2 RBD may make it easier to interact with the ACE-2 (receptor) by enhancing the

quantity of atoms implicated in the binding process. The longer capping loops and the altered amino acids could be the root of greater SARS-CoV-2 binding energies than SARS-CoV. Advanced affinity levels may be linked to the dynamics of infection and the virus's alleged quick spread. The SARS-CoV-2 that caused SARS has not been fully explained. While this analysis was continuing, another study found a substantial RBD protein homology between *Rhinolophus affinis* Subsp, pangolin, and SARS-CoV-2 coronavirus isolates [16,17]. In addition, the researchers hypothesize that Pangolin, which shares 97.99% of the virus's binding affinity pattern with humans, could serve as a bridge between bats and humans. Additionally noticeable are the loops in the RBD, and RaTG13's spike structure is strikingly comparable to that of SARS-CoV and SARS-CoV-2. The protein sequence of the receptor binding motif contains five essential amino acids.

The sequence of SARS-CoV-2 differs from the pure viruses from pangolin and *Rhinolophus affinis* by 1 and 4 amino acids, respectively, in the amino acids assumed to be essential for the union with ACE-2 [18-20]. As shown in our work, these changes should lead to a slightly less favorable contact affinity between such viruses and ACE-2 than SARS-CoV-2. As a result, in addition to the amino acid changes, the loops present in the SARS-CoV-2 Spikes may be essential for defining the host receptor sensitivity of the viral Spikes. Overall, fundamental modifications and changes to the viral Spikes residue composition may improve the kinetics of viral infections and their spread.

Conclusion

It is concluded SARS-CoV-2 and the human cell receptor ACE-2 have an interaction. SARS-CoV-2 pathogenicity is increased by switching from CCR5 to CXCR4 as the co-receptor. These modifications affect the receptor's capacity to interrelate through human ACE-2 (receptors) and enhance identification. The presence of two loops throughout the SARS-CoV-2 RBD may facilitate ACE-2 receptor binding via enhancing the quantity of atoms implicated. The reason SARS-CoV-2 greater binds to substrates with higher binding energies than SARS-CoV may be due to longer capping loops and changed amino acids.
